### Abstract

This work establishes through statistical analyses the relationship that exists among the major and trace elements in the Maastrichtian Coal Measures of Southeastern Nigeria. Laboratory analyses were performed using the inductively coupled plasma-optical emission spectrometry (ICP-OES). Two distinct populations were deduced; the first population represents rocks from a detrital suite dominated by quartz and clay minerals. The second suite comprises the coal samples deposited in the peat swamp. These suites are unrelated because there is no transition from one to the other. The geological interpretation of factors/components yields insight into the association of major and trace elements in the rocks of the Maastrichtian coal measures and main phases that govern the distribution of geochemical variables.

---

### 1. Introduction

The Anambra Basin comprises mainly of sedimentary rocks (sandstones, siltstones, mudstones and shales) and occupies the lower section of the Benue Trough. The basin is richly endowed with sub-bituminous coal seams which are found within the Mamu and Nsukka Formations of Campanian-Maastrichtian age. A number of studies have concentrated on the stratigraphic sequence of the Anambra Basin [1-3]. There has been limited number of research work in terms of utilizing the major and trace elements present in the sediments of the Coal Measures, to determine the processes responsible for their geochemical distribution.

A number of authors have concentrated mainly on the abundance and distribution of elements in the Nigerian coal. For instance, [4] determined major, minor, and trace elements in three Nigerian coals (Okpara, Onyema and Ekulu mines) [5], analysed 24 samples from the Enugu coal deposit for eleven elements using the Particle Induced X-ray Emission (PIXE) and Rutherford Backscattering (RBS) techniques [6], compared the quality of coal (raw and washed), coke char, coke, and briquettes from eight Nigerian mines (Onyeama, Ogbete, Enugu, Gombe, Asaba-Ogwashi, Okaba, Afikpo and Lafia) using cluster analysis [7], analyzed the metal contents and concentrations of an unspecified number of Nigerian coal samples using atomic absorption spectrophotometer (AAS). By employing (lithium metaborate/tetraborate fusion), inductively coupled plasma optical emission mass spectrometry (ICP-OES), combustion infra-red (LECO) and modified acid-base accounting, [8] investigated the potential of the coal and coal-bearing units of the Lower, Middle and Upper Benue Trough to produce acid mine drainage conditions [9], applied epithermal neutron activation (ENAA) in combination with principal component analysis

elements on a combination fusion technique followed by ICP-OES analysis using a Thermo Jarrel Ash Enviro II simultaneous/sequential ICP.

For trace element analysis, 0.25 g of the sample was digested with four acids beginning with hydrofluoric, followed by a mixture of nitric and perchloric acids, heated using precise programmer controlled heating in several ramping and heating cycles which takes the samples to dryness. After dryness is attained, samples are brought back into solution using hydrochloric acid. The sample solution was then analysed for elemental concentration using a Varian Vista Pro inductively coupled plasma-optical emission spectrometry (ICP-OES). Calibration was performed using USGS and CANMET certified reference materials.

### 3.2 Statistical Analysis

The elements were subjected to univariate (minimum, maximum, mean and standard deviation, correlation coefficient) and multivariate (factor and principal component analyses) statistical analysis with the aid of the SPSS 16.0 for Windows (SPSS Inc., Chicago, IL, USA, 2007). Since most of the measured parameters were not normally distributed, the Spearman's rank correlation was used to examine the correlation between elements. The correlation coefficient matrix measures how well the variance of each constituent can be explained by relationship with each other. Factor analysis (FA)/Principal Component Analysis (PCA) were applied on experimental data standardized through z-scale transformation in order to avoid misclassification due to differences in the units of measurement. Standardization tends to increase the influence of variables whose variance is small and reduce the influence of variables whose variance is large <sup>[10]</sup>.

## 4. Results and Discussion

### 4.1 Major elements

Table 2 summarises univariate statistics, performed on the measured parameters in terms of their minimum, maximum, mean and standard deviations (S.D.). Samples with minimum values below the detection limit (D.L.) were replaced with half the value of the detection limit and applied for further data processing. Results obtained for samples of 10 major elements shows that SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>T account over 75% composition (Table 2). This is in general agreement with

the results from previous work in the Benue Trough [8]. The high concentration of SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> indicate high detrital quartz and clay mineral content in the rocks of the Coal Measures.

The data set was screened to identify outliers. This was achieved by the evaluation of the elements displayed in boxplots (Figures 4 and 5). With the exception of SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Na<sub>2</sub>O and K<sub>2</sub>O the other measured elements were not normally distributed, therefore the non-parametric Spearman's which applies the ranking order of variables was utilized in the determination of the correlation coefficient.

Table 2 Descriptive Statistics of major elements

Variable	Min	Max	Mean	S.D.
%				
SiO <sub>2</sub>	1.02	96.41	62.18	27.11
Al <sub>2</sub> O <sub>3</sub>	0.66	30.90	11.24	7.86

Correlation matrix aids in identifying association between variables on a general basis (Table 3). A probability value of  $p=0.05$  was considered as statistically significant in this study. One interesting feature of the correlation matrix is the lack of correlation between SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> indicating that much of the SiO<sub>2</sub> is not associated with the Al<sub>2</sub>O<sub>3</sub>. This is probably due to the fact that much of the SiO<sub>2</sub> is present as quartz. This interpretation is supported by the exceptionally high SiO<sub>2</sub> values and also by a strong correlation between SiO<sub>2</sub> and ash yield. The low and negative correlation of SiO<sub>2</sub> with Al<sub>2</sub>O<sub>3</sub> ( $r=-0.330$ ) and Fe<sub>2</sub>O<sub>3</sub>T ( $r=-0.260$ ) imply the occurrence of these oxides in different rock types. The correlation matrix was further subjected to multivariate statistical analysis to provide a better understanding with respect to the relationship existing among elements and the probable processes responsible for their formation.

Factor analysis was performed on the correlation matrix for the major elements of the different sites. This was to identify the relationship among the measured elements. The variance/covariance

and factor loadings of the variables with eigenvalues were therefore computed (Table 4). There appeared to be overlaps among the factors thereby necessitating further analysis. This was achieved by rotation of the axis producing a new set of factors. This was attained after 5 iterations. Each factor involved a sub set of the original variables with as much as possible minimal overlap (Table 5). Since the differences between the unrotated and rotated components were significantly different, the rotated option was used for further analysis. The components were further sorted with the exclusion of values less than 0.500.

Cumulative %	26.55	49.71	72.19	86.38

Component 1 is responsible for 27% of the total variance with  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$  and  $\text{P}_2\text{O}_5$  as the dominant oxides. From the correlation matrix, there exist strong and positive correlations between  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  ( $r=0.844$ );  $\text{Al}_2\text{O}_3$  and  $\text{P}_2\text{O}_5$  ( $r=0.810$ ). The presence of  $\text{TiO}_2$  and  $\text{P}_2\text{O}_5$  are indicative of basaltic rocks of oceanic environments. Components 1 and 2 comprise the phyllosilicates which form building blocks for most clay minerals<sup>[11]</sup>. Component 2 which accounts for 23% of the total variance and shows high correlation between  $\text{Fe}_2\text{O}_3$  and  $\text{MnO}$  ( $r=0.818$ ), Component 3 explains 22% of the total variance consisting mainly of alkali oxides with high correlation between  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  ( $r=.852$ ). Component 4 contributes 14% to the total variance with  $\text{SiO}_2$  and  $\text{CaO}$ .

The strong correlation between  $\text{Fe}_2\text{O}_3$  and  $\text{MgO}$  ( $r=0.717$ ),  $\text{MnO}$  ( $r=0.818$ ) and  $\text{CaO}$  ( $r=0.624$ ) indicates that these elements are present in carbonates, probably siderite as the mean for  $\text{Fe}_2\text{O}_3$  is greater than the total of  $\text{MnO} + \text{MgO} + \text{CaO}$ .

#### 4.2 Trace elements

25 trace elements were subjected to fusion inductively coupled plasma (FUS-ICP) and total digestion - inductively coupled plasma (TD-ICP) analyses. Out of all the samples analyzed for, Bi, Tl and W were below the detection limit and were thus excluded from further analysis (Table 6). The Spearman's was applied to determine the correlation coefficient between trace elements (Table 7). Correlation matrix was further applied in FA. The initial application of FA produced overlap in factors for Y and Ag (Table 8). Rotation of the axis of the initial factors after 12 iterations produced a new set of factors (Table 9). With the exception of Pb, the other elements produced minimal overlap, indicating dual sources contributing to the presence of Pb.

( ) Number of samples below detection limit

Components 1 and 2 explain 52% of the total variance for trace elements in the dataset and accounts for majority of the analysed trace elements. The inferred host phases for component 1 are a mixture of lithophiles (Sc, Be, V, and Cr; with  $r = 0.699-0.986$ ), chalcophiles (Cd, Cu, Ga, Te and Zn; with  $r = 0.561-0.751$ ) and siderophile (Co, Mo and Ni; with high  $r = 0.820-0.906$ ). Component 2 has a combination of lithophiles (Y and Zr) and chalcophile (Ag). The first two

components indicate the different sources of trace elements in the Maastichtian coal measures. Component 3 accounts for 11% of the total variance and is made up of lithophiles (Ba and Sr) while components 4, 5 and 6 comprise mainly of chalcophiles.

## 5. Conclusion

The Maastrichtian coal measures in the Anambra Basin were investigated for their geochemical elemental associations. Geochemical analyses have shown through statistical correlation of major and trace element contents that the coals and non-coal strata belong to two distinct unrelated populations. The first population is clearly derived from the clastic rocks in the sequence. It represents a simple, two end-member mixing model. One of the end members is nearly pure quartz (960.4 % SiO<sub>2</sub>) with very minute amounts of the trace elements. The other end member has minor amounts of clay and perhaps accessory detrital minerals and accounts for the majority of the trace elements.

The second population comprises the coal samples. The trends of these coal samples are fairly typical - the higher the ash yield, the higher the element concentrations. The two suits are unrelated because there is no transition from one to the other in any of the diagrams. There is a gap with no ash yield values between about 35 to 60%. The first suite represents periodic flooding and killing of the peat swamp from a source that is not the regular source of detritus particles deposited in the peat swamp. However, it is therefore recommended that further studies and more detailed stratigraphic and geochemical analyses be carried out within the study area.

## Acknowledgements

The service rendered by the Geological Survey Agency of Nigeria, Kaduna, is acknowledged in the provision of core samples used in this study. The authors are also grateful to the Activation Laboratories, Ontario, Canada, for the analysis of the entire samples
